# TIIE EXTERNAL MALE GENITALIA OF SOME RHYNCHOPHORA* 

ARTHUR F. PRUHN
Dixie College, St. George, Utah

## INTROUUCTION

Today there is an increasing recognition among taxonomists of the importance of consideration of the complete morphology of insects in classifying them and in arranging them in their logical phylogenetic sequence. Regarding the Rhynchophora, with which this paper is concerned. some progress toward a more complete understanding has been made. In 1912 Sharp and Muir made a study of the male genital tube of the Coleoptera in general and observed that the various specializations they noted in the forms of Rhynchophora examined would doubtless be of future significance. Tanner in 1927 made a similar important study of the female genitalia and subsequently has included both the male and the female genitalia in descriptions of new species, as noted in his study of the subtribe Hydronomi. Stickney in 1923 examined and reported his findings on the head capsule. Boving and Craighead in 1931 published the results of their studies of the larval forms. Ting in 1936 reported the results of a rather comprehensive study of the mouth parts of the Rhynchophora alone.

The purpose of this study has been twofold:

1. To examine the external genitalia of as many varied forms as time would permit and to interpret, insofar as is possible, the phylo-genetic relationships that exist. It is also proposed to determine to what extent the results of this study are in agreement with investigations that have been made concerning other parts of the anatomy of Rhynchophora.

[^0]2. To determine if the morphological differences that exist between the genitalia of different species within he same genus are significant enough to warrant serious consideration of this structure in classification.

## \CKNOWLEDGMENT

I wish to express my gratitude to Dr. Vasco MI. Tanner, head of the Department of Zoology and Entomology, Brigham Young University, who suggested this study, for his consideration in providing the insects and much of the literature, for his valuable assistance and advice as the study progressed. for his tolerance during the early stages of the study when a satisfactory technique of dealing with the material had not been developed. and for other kindness too numerous to mention. Thanks also for the encouragement and consideration I received from the students in the department with whom I have had the priviledge of working.

## SPECIES STUDIED

The following species that have been studied are listed as they appear in the first edition of Leng's Catalogue of the North American Coleoptera along with the two species from the Istands of the Pacific. Family Prentidae

Eupsalis minuta 1)rury. Figs. 3 a \& b.

## TECHN゙IQUE

＇The Rhynchophora examined were museum specimens from the collection at the Brigham loung University．The insects were relased by placing them in water and heating it，often to a boil．The abdomea was then removed under a binocular microscope and was placed in a solution of canstic potash，the strength of which was determined by the condition and the age of the specimen．The structure was boiled lons enough to remove the fat and muscles．The tergites were removed from the ablomen，exposing the internal structures to full view in－situ．With a pair of hair－spring tweezers the structures were protruded from the abolomen．Since the study was concerned only with the morphology of the external genitalia no attempt was made to study those structures that normally lie within the abobmen during copulation．However，the testis and the cjaculatory duct were noted in many species．

Within the external genitalia are chitmized struts of varying length，the median struts of the median lole and the tegminal struts． （）Cten parts of these struts rested within the abdomen after the struc－ fures had been fully evaginaterl．Th order to show them in their en－ tirety．therefore，it frequently became necessary to detach the genital tule from the aldominal wall．

## GENERAL MORPHOLOGY

The external genitalia of the Rhynchophora consists essentially of a tulue，part of which is drawn within itself and has become chitinized In varying degrees．The minermost tube eatends anteriorly where it joins another smaller tube of different origin，the ejaculatory duct， Which extends into the abdomen where it branches to the testes．The outermost tube，which makes up the copulatory apparatus is atacher to the eighth abdominal segment．

The origin of the external male genitalia has been the subject of much study and conjecture．Sharp and Muir speculated that since the genital tube lies posterior to the anus，no tergite could reasonably enter into its composition．They further assume that since the eighth sternite is the last plamly visible，the chitinized ${ }^{\top}$ shaped rod（spiculum gas－ trale）that is found on the floor of the abdomen represents the ninth stornite．

Suodgrats states that the membrance which makes up the genital fulse is the posterior part of the venter of the ninth primary somite， with the $I$ shaped rod（spiculum gastrale）representing the 9 th ster－ nite．Ife locates the anus within the dorsal remmant of the tenth．

Metcali traced the development of the external genitalia in one of the curculionids, Anthonomus pomorum L. and in three other specics of Coleoptera. The conclusions are not at wide divergence with those of Snodgrass or the speculations of Sharp and Muir. Ly making longituthial sections of the developing genitalia in both the larval and pupal stages Metcalf was able to trace the deevlopment of the tube includins the formation and the chitinization of the varions segments into which it subsequently becomes divided. On the basis of these investigations: and a thorough review of the literature, including the work of foreign investigators. Metcalf has concluded that the external genitalia, including the spiculum gastrale that lies within the abdomen during copulation, develops from the endopodites of the ninth sternite ant that, as such, this structure is homologous with the parameres of other insects.
lon the adult, then, the external genitalia is attached to the eighth abdominal somite. When at rest the tube lies folded upon itself within the abolomen, being extruded at the time of copulation. Figure 1 illustrates the general form and method of attachment of the genitalia of Phytonomus posticus Gyll. one of the curculionids as it appears when extruded from the abdomen by the artificial method described. Viewed from both the dorsal and the lateral aspects the relationship of the various structures to each other can be discerned.

Insofar as it has been possible the terminology used to designate the various parts of the external genitalia is that used by Bissell in his paper on the study of the reproductive system of the pecan weevil. When terminology other than that used by Bissell was needed, the work of. Sharp and Muir was relied upon. In the main the names used in the two studies are in agreement with specific differences noted as they occur. One term, inter-aedeagal structures, was coined by the atuthor.

In a normal extruded genital structure the most posterior part of the tube is the median lobe ( ml ) which is essentially a chitinized portion of the tube itself. This structure varies considerably within the Rhynchophora from a simple trough in the Scolytidae and some Curculionidae to paired "plates" in the Brenthidae and others. Often these "plates" do not resemble such structures at all but are referred to as such for the purpose of clarity and miformity.

Attached to, or articulating with, the median lobe are paired rods called the median struts (ms) that extend anteriorly. Their size, shape. and their method of attachment is variable. Bissell points out that these structures serve as points of attachment for some of the muscles used to manipulate the structure.

Within the median lobe, generally in a membraneons area, is the median orifice (mo). This marks the place where the tube folds bate within itself. The innermost tube is refered to as the internal sae (is). Sharp and Muir have indicated that in Sphenophorus obscurns this sate develops as an extension of the genital tube, and that it is not evagimated into the median lobe until the pupa is ready to emerge. This being the case the median orifice is often very difficult to locate, particularly in the smaller specimens. The lines in the figures used to indicate the location of this opening do not necessandy indicate its size and shape since this is often impossible fo determinc with accuracy. OEten the median orifice is bordored by one or two chitinized plates: the orificial plates (op). Their presence aids materially in the location of the orifice.

The ape of the internal sac where it connects with the ejaculatory duct (ed) is called the flagellum (f). ln many species parts of the llagellum as well as parts of the internal sac are chitinized in various ways and to different degrees. Since these chitinized areas are not uniform, and since no name has been applied to them, I have labeled them ats inter-atedeagal structures (int. st.) since they oceur in varying positions within the genital tube, which bissell has called the aedeagus. la two species, Khimoscaphia leguillomi Guer. and lhycerus noveboraconcis (Forst.) this sat has been evaginated by grasping its sides through the median orifice and pulling it outward. This structure has been noted in connection with the narrative descriptions of both species and in one it has been illustrated.

Sometimes the ejaculatory duct can be discerned at its point of attachment to the hagellum and occasionally it can be traced throughout much of the adeagus, but more often it cannot be identified with certainty beneath the membrane. At times the internal sac is not easy to locate, sometimes it camot be scen. This is particularly true in those structure where the median lobe is tube-like or where the edges are inllexed dorsally. In some species the sac extends well beyond the ends of the median struts while in others it is very short. Sharp and Muir have indicated that during copulation in some species the internal sate is evaginated and consider this behavior to be the seneral rule. Since $n 0$ species were observer in copula no additional light can be thrown on this by this study.

Anterior to the median lobe is another chitinized structure, the tegmen ( tg ) which may be present as a simple ventral plate, as a fork, as a simple ring with a ventral strut, or a ring with a strut ventrally and pared lobes or a pronounced cap-piece on its dorsal surface. The
ventral strut when present is referred to as the tegminal strut (ts).
Connecting the tegmen to the median lobe is the second connecting membrane ( cm 2 ) referred to as the first comecting membrane by Sharp and Muir, Metcalf \& Wilson. Since it is customary to number the abdominal segments from the anteriar to the posterior, it seems reasonable that the comecting membranes should be numbered in a simitar manner. Therefore the system of Bissel is adopted in this paper and the most posterior will be called the second. The membrane which commects the tegmen with the abdominal wall is the first connecting membrane ( cm 1 ). In those forms where the tegmen is Y shaped or reduced to a ventral plate, the two membranes are continuous dorsally and laterally. In such cases the separation of the two is an arbitrary one, based on their location in relation to the tegmen. A similar situation is noted when the dorsal portion of the median lobe is membranous. This membrane is essentially a posterior extension of the second comecting membrane and is referred to as such, although it is recognized as being a part of the median lobe.

In some forms (Calendrinae) the first connecting membrane has become chitinized to varying degrees to form a "sleeve" around the tegmen. The degree of this chitinization is variable and sometimes is so slight that it is difficult to distinguish it from the adjoining membrane.

In many of those forms that possess a dorsal cap-piece or have paired lobes on the tegmen, the first connecting membrane is attacheil in such a manner that the ends of the cap-piece, or the lobes, are pulled upward and sometimes completely over as the aedeagus is drawn from the abdomen. Whether such an extreme condition as this occurs during copulation is questionable, but this adaptation is doubtless of some value during the performance of that act.

Within the abdomen, and lying on its ventral wall is a third chitinized structure referred to by Sharp and Muir as the "spicule" and by Wilson, Bissell and Metcalf as the spiculum gastrale ( sg ). Metcalf insists that this structure arises as a part of the aedeagus and that it serves as a basis of attachment for the powerful muscles that manipulate the external genitalia. Since it is normally not extruded with the external genitalia it has not been included in this study. An exception to this exists in the Calendrinae where, as a simple rod, it is attached to the ventral surface of the chitinized "sleeve" from which it extends anteriorly and slightly dorsally.

```
ENPLNNATIONO! PJ, OJES
```

All drawings were made with the camera hucida attached to a binocular microscope. The drawings of Apion were doubled in size with dividers after the original tracings were mathe. Those areas that are stippled represent membane. on very light chitin that canot readily be distinguished from the membrane adjacent to it. Where this situation exists it has been noted in the narative descriptions of the species involver. Those areas that are chitmized are indicated in wo ways. either a selicl black line or as clear areas. The choice of which to use has largely been dedemined by the comparative size of the structures involved as viewed from both the domal and lateral views. Dashed lines are generall! used to indicate the burders of the internal sate and the sacs themselves are stippled more densely than the other membranoms structures. The straght lines on the right side of the paired figures represent 1 mm .

Is has been previously noted, it became necessat? We detach sombe of the structure from the alofonen in order to see the anterior terminus of the median and tegminal struts. Therefore for the sake of uniformitg, all structures, with the exception of Figure 1. have bees illustatatel in that manner. hat is their point of attachment to the athdominal wall has not been shown since it diel not appeat w serve any particular purpose 10 inchucle it .

In the following descriptions the various species that were enamined have been grouped in what seems to be their most logical sequence on the hasis of the external genitalia alone. It will be noted What the fanily Platystomidae is described following a group that includes some of the Sub-familie of Curculionidate ateording to the arrangement of Leng's Catalogue and that other Sul)families of Curculionidate follow the platystomids. The reatoms for this arrangement are noted later in the paper.

In the ligures those that are labeled "a" represent the dorsal view of the structure and those that are labeled " ${ }^{\circ}$ " indicate that the figure illustrates the lateral aspect. The following aboreviations have been userl:

> Family Pelababe

The median lobe consists of two chitinizel portions, the fower in a shallow wough, the enper a shoge strap-like piece that terminates in a L shaped loup beyome which the membance potrurles. This membratce comtans the median wrife which is tanked by orificial plates. The dorsal strap piece forks atteriorly, cach fork joining with a lateral extension of the ventral plate of form the median struts. The tegmen is a ring with a dorsal capppicce which is roughly $I$ shapect, the athterior forks of which are hirsute. The internal sate extends beneath and anteror fo the tegmen. Bi carerul mamipulation with hatr-spring tweezers the sat in this species was exagimated. It is fonger than the
 nized strip that extends into the latgellum and on into the efaculatory duct. This may be a lattenced chitin tule since it appears very loosely attached to a membrathe. Nown midlaty lotween the latgellum and the median orifice are las peruches, whe dorsal amel one sentral that pro ject laterally: 'These pouthes are bracel on their maryins ber narow strips of chatin which form a $\backslash$. It is entirely possible that these serve as claspers daring coptuation or that the sac is normally not evaginaterd as far ats it was by the artificial meaths used and that these are nsed in transferring sperms into the spermatheca of the femate.

## Family bkENTmae

Characoterstace of the Fambey: The median lobe comsists of [wo plates. the lower is a shallow trough, fully chitinized latemally, but with a membrane or light chitin ventrally near the median line. The upper plate is chitmized laterally and apically. the center being either membrane or extremely light chitim. The median orifice is located in the terminus of a membranous pouch that extends posteriorly from heween the two plates. It is fanked by orificial plates. The median struts fork posteriorly with one branch of each comnected to the lateral edges of the dorsal and ventral plates respectively. The tegmen forms a $Y$ ventrally with the forks articulating with the ventral projections of a dorsal cap-piece which is deeply forked posteriorly cach of the forks hirsute near the apex. Tuside the lateral edges of this cap-piece is a small chitin strip that is attached to the median struts on either side and serves to bind the tegmen to the median struts. The first connecting membranc is attached in such a manner as (o) pull the hirsute
ends of the cap-piece upward as the aedeagus is drawn from the abdomen. In both species the ejaculatory duct is visible as a small chitinized tube which enters the flagellum near the anterior end of the aedeagus.
Fupsulis minuta Drury. Figs. 3 a \& b.
The ventral plate of the median lobe is chitinized laterally, blending to membrane near the center. The dorsal plate is narrowly chitinized peripherally the balance being entirely membranc. The cappiece of the tegmen is deeply forked and the hirsute ends are rather pointed:
Eictocemus 10-maculatus Montr. Figs. 4 a \& b.
The vental plate of the median lobe is chitinized except for a very narow strip mid-ventrally. The dorsal plate is largely chitin except For a membranous lumen medially. The median struts and the tegminal struts are both rather large. The hirsute forks of the dorsal cap-piece are romded.

## Family Curculionidae:

Lub-families: Rhynchitinae, Attelabinae, Pterocolinat. Cyadlinate. Genus Notaris (Curculioninae).

CHaracteristics of the Group: The median lobe consists of $w$, plates, the amount of chitinization of both variable. The median struts are forked posteriorly, one branch attached to the lateral edges of each of the plates. The tegmen is a ring with a dorsal cap-piece which normally projects posteriorly although it is sometimes pulled upward and anteriorly by the first connecting membrane as the aedeagus: is drawn from the abdomen. The cap-piece has either a single or a double lobe.

Rhynchites bicolor zuickhami Ckll. Figs. 5 a \& b.
The lower plate of the median lobe is very lightly chitinized medially. The upper plate is narrow and thin, the chitin blending into membrane laterally. The median orifice lies below and behind the apex of this plate. The dorsal cap-piece of the tegmen was pulled anteriorly by the action of the first connecting membrane in some specimens of this species. Cap-piece is hirsute terminally.

Khynchites aeneus lioh. Figs. 6 a \& b.
The lower plate of the median lobe is chitinized ventrally, the upper is rather broad. The median orifice lies in the membrane between the two plates at their apex. Tegmen, as drawn, illustrates how
the first connecting membrane pulls the cap-piece anteriorly as the ateragus is drawn from the abdomen. Cap-piece is hirsute terminally.

Ittelabus bipustulatus Fab. Figs. 7 a \& b.
The lower plate is rather heavily chitinized ventrally and is about halif the length of the rather broad upper plate. The median orifice lies in the membrane between the two plates near their apex. An interaedeagal structure lies in the tlagellum. Cap-piece is hirsute terminally.

I'terocolus ovatus (Fab.) Figs. 8 a \& b.
The lower plate of the median lobe is chitinized laterally with light chitin present on its ventral surface near the tip. The narrow upper plate is chitinized. The median orifice is located in the terminus of the membrane which lies between the two plates. The cap-piece with a single lobe is directed posteriorly. The internal sac can be tracer throughout the body of the aedeagus.

Cylas formicarius (Fab.) Figs. 9 a \& b.
The ventral plate of the median lobe is chitinized laterally and peripherally, but is membranous medially. The dorsal plate is very narrow and rounded at the apex. Between the two plates apically and within the membrane the median orifice is found. An inter-aedeagal structure is present within the internal sac. A double forked cap-piece which normally points posteriorly was inverted by the action of the first connecting membrane as the aedeagus was drawn from the abdomen lies dorsally on the tegmen. The internal sac can be traced throughout the structure and anteriorly the ejaculatory duct can be discerned entering the flagellum.

Notaris puncticollis (Lec.) Figs. 10 a \& b.
The lower plate of median lobe is chitinized laterally, terminally and lightly so medially. Dorsally this plate is largely membrane with a single orificial plate overlying the median orifice. The upper plate is narrow, and short with the chitin confined to the periphery. The tegminal cap-piece which was inverted by the action of the first connecting membrane is slightly notched apically with the notch filled in with much lighter chitin which rounds off the structure.

Notaris aethiops (Fab.) Figs. 11 a \& b.
The lower plate of the median lobe is broad, short and fully chitinized ventrally and laterally. Dorsally this plate is largely membranous with a pair of orificial plates near the terminus which flank the median orifice. The upper plate is short, pointed and chitinized on the
periphery only：The cap－piece of the tegmen is madivided with a slight incurving at the tip．The cap－piece wats prevented from being inverter durng evagination leg hokling it firmly the rest of the structuse with the wee\％rs．The intemal sac and the çaculatory duct are very avident anterionly．

## Family I＇LiTV：Tombode

 scoop－shaped structure which is chitinizel vemtally and laterally．Dom－ sally bhe secomb combeching membrathe extemes to the aper where the median orifice is fomme overlan ley orificial plates or a plate．The median struts are attached to the dorsal and lateral edges of the median lobe．The tegmen is a ring with a single dorsal cap－piece which nor－ mally profects posteriorly．The cap－piece is spate shaperl．The teg－ mimal strut is fery shome．

 No intemal sate can be discemed．

## fion lurbulcutum Sm．ligs．It a \＆

The median lobe appears to be a tube composed of lightly chiti－ ni\％ed material．The merlian orifice conld mot be located．The median struts are attached to the dorsal anterion edge of the median lobe．The tegmen is a ring with large dorsal capprece which terminates poste－ rionly in a double point and anterionly in a single one：The comecting membrane that was discermable moler a compomel microscope is frag－ mental．

Ifion pennswianicum boh. Figs. 15 a \& b.
The merdian lobe appears to be a chitinized trough. I entrally and baterally the chitin is rather evident, but dorsally the medial area that is indicated as being membranous may in reality be light chitin. ("ortainly it is of different consistency than are the edges or the bottom of the bough. The median orifice has been tentatively located in this membranous (?) area. The median struts are attached to the lateral edges of a short dorsal extension of the median lobe. The tegmen is a ring with a dorsal cap-picee which is rather bluntly peinted pestro riorly and rather sharply pointed anteriorly. No connceting membranes were discerned on any of the speciments of the species that were examined.

CHARACTERETICS OF THE TWO SUB-FAMHLEG: No shatp line of demareation exists between these two sub-families ats they are listed in Leng's Catalogne. Some of the members of one group appear chosely akin to those of the other on the basis of the external genitalia. Comsequently they will be described as one group, within which there is much variation.

The median lobe is either a simple trough or a tule. The tegmen maty be a Y , a ring, or a ring with lobes. ()ften the internal sac is impossible to discern. The first and second connecting membrames often camot be separated dorsally, but literally and ventrally they are divided by their attachment to the forks of the tegmen.

1) Pslobus *'asatchensis Tanner. Pigs. 16 a \& b.

The median lobe is a chitinized tube as long as the second connecting membranc and rather pointed apically from the lateral aspect. Mid-dorsally there is a depression in the chitin immediately anterior (1) which the internal sac protrutes with a single orifical plate overlying it. The metian orifice is in the ip of this pouch. The tegmen is a ring with short, pointed projections that were anteriorly ats the ate asus was drawn from the abdomen.

Eupagoderes sordidus (Lec.) Figs. 17 a \& b.
The heavier chitin of the metian lobe forms a trough, but middorsally there is a membranous area which contains the medial orifice which is overlain by a single orificial plate of light chitin. Anterior to this membrane a light chitin band connects the two sides. The median struts are attached to a mirl-lateral extension of the median lobe. The
tegmen is a ring with two small lobes that are pulled upsard by the first connecting membranc.
Eudiagogus pulcher Fahr. Figs. 18 a \& b.
The median lobe is a short, round, chitinized tube the sides joinel (?) together with the point of this juncture (?) very evident. The median orifice can easily be discerned in the membranous area at the tip, of the tube. Median struts are attached laterally to a ventral platelike extension of the median lobe. The tegmen is a ring. sightly lobed dorsally:
Khinoscapha leguilloui Guer. Figs. 19 a, b \& c.
The median lobe is a chitinized tube which is longer than the second connecting membrane. Immediately behind a posterior dorsal depression of the lobe is a membranous lumen with the median orifice situated in its apex. The median struts appear as lateral extensions of the ventral aspect of the lobe. The tegmen forms a ring with the Hagellum normally pointing posteriorly, but which have been pulled to an anterior position by the first comecting membrane as the aedeagus was pulled from the abdomen. The internal sac has been pulled from its position and is shown in Figure 19 c. Various parts of it are chitinized as is indicated. It is probable that those chitinized structures which are noted in many species and termed inter-aedeagal structures are similar chitinized parts of the internal sac.

Tanlimecus confertus (Gyll.) Figs. 20 a \& b.
The median lobe is a chitinized trough the lateral edges extendins dorsally and medially leaving a narrow extension of the second connecting membrane rumning down the center. A rather large median orifice marks the terminus of this membranous area. Median struts are attached to the ventral lateral edges of the median lobe. The tegmen is a ring with two projections which were pulled upward by the lirst connecting membrane. Inter-aedeagal structures are present within the flagellun.
Maydalis gentilis Lec. Fïgs. 21 a \& b
Ventrally and laterally the median lobe is chitinized, the lateral edges inflexed some what dorsally. The balance of the dorsal surface is occupied by a posterior extension of the second connecting membrane which contains the median orifice near the apex. Paired orificial plates are found immediately anterior to the orifice. The median struts are short extensions of the sides of the median lobe. The tegmen is a ring with paired cap-pieces which project posteriorly.

Maydalis leconlei lemehrosa Fall. Figs. 22 a \& b.
Ventrally and laterally the median lobe is chitinized, the lateral edges somewhat intlexed dorsally: The balance of the dorsal surface is occupied by a posterior extension of the second connecting membrane which contains the median orifice near the apex. Paired orificial plates which are attached to the sides of the median lobe and appear as lighter continuations of it. The median struts are short extensions of the sides of the median lobe. The tegmen is a ring with pairerl calpieces that project posteriorly.
Odonlocorymus sculellum-album (Say). Figs. 23 a $\& 1$.
The median lobe is lightly chitinized ventrally. much more densely so laterally. Dorsally the second connecting membrane extents throughout the entire distance of the median lobe and beyond the terminus of the chitinized sides for some little distance. The median orifice cannot be located with certainty, but it appears to be situatied in this membranous tip. The median struts are attached to a ventral plate-like extension of the median lobe. The tegmen is a ring with paired and pointed cap-pieces that have been pulled anteriorly hy the first connecting membrane as the aedeagus was drawn from the abolomen. The internal sac can be traced posteriorly as far as the median lobe.

Dorytomus brevisctosus Csy. Figs. 24 a \& b.
The scoop shaped median lobe is chitinized ventrally and later ally. Dorsally the second connecting membrane extends into the median lobe to near its apex where it bears the median orifice which is Hankerl by two small orificial plates. Median struts are attached to a smail ventral plate-like extension of the median lobe. The tegmen is a ring with paired and pointed cap-pieces projecting posteriorly. Within the internal sac is a chitinized tube, probably an extension of the cjaculatory duct, which can be followed posteriorly to near the median orifice.

Lixus terminalis Lec. Figs. 25 a \& b.
The median lobe is chitinized ventrally and laterally. On the dorsal-anterior edge the sides meet, but do not join. Posteriorly an ever-widening membrane lies between the sides at which terminus the median orifice is found. An inter-aedeagal structure that marks the anterior end of the internal sac is located within the median lobe. The median struts are short extensions of the lateral edges of the median lobe. The tegmen is a ring with short dorsal knobs that project posteriorly.

Jinocleus alborestitus Csy. Figs. 26 a \& b.
The median lobe is densely chitinized ventrally and laterally. Dorsally the chitin is much lighter and occupies most of the area between the heavy chitin sides. The median orifice is located in a membranous area near the tip and is flanked by orificial plates. The median struts are short extensions of the sides of the median lobe. The tegmen is a ring with two short dorsal knobs which project posteriorly. The tegminal strut is very short.

Cleonus culandroides (Rand). Figs. 27 a \& b.
The median lobe is densely chitinized ventrally and laterally. Dorsally and anteriorly there is membrane which blends soon into chitin which is considerably lighter than that at the sides. No membranous area is found apically, rather the median orifice seems to be present bencath the chitinized cover near the apex. The median struts are short extensions of the lateral edge of the merlian lobe. The tegmen forms a simple ring with a slight notch in the mid-dorsal surface.

Mononychus z'ulpeculus (Fab.) Figs. 28 a \& b.
Ientrally the median lobe is chitinized at the periphery. a light chitin strip comnecting the heavier sides anteriorly. Dorsally the chitin is confined to the sides and to a rather pointed apex. The second com. necting mombrane extends well into the median lobe dorsally with the location of the median orifice questionable. It appears to be about two-thirds of the way loack from the apex. Tmmediately behind, and within the internal sac, is a lightly chitinized inter-aedeagal structure. The median struts articulate with ventral-lateral extensions of the median lobe. The tegmen forms a substantial ring.

Colecertis marmoratus Horn. Figs. 29 a \& b.
The metlian lobe is trough like, chitinized ventrally and laterally: The second connecting membrane extends into the lobe dorsally and terminates near the apex where the median orifice is located. Orificial plates flank the orifice. Median struts are attached laterally to a ventral plate-like extension of the median lobe. The tegmen forms a thin ring around the median struts.

Palaninus baculi Chitt. Figs. 30 a \& b.
The median lobe is long, narrow, and chitinized ventrally and laterally to form a trough. Dorsally the second connecting membrane extends to near the apex where the median orifice is located. It is flanked by orificial plates. The median struts are attached to a ventral plate-
like extension of the merlian lobe. The tegmen forms a thin ring. its strat rery short.
Inhonomus grandis lioh. Figs. 31 a \& b.
The median lobe is a shallow chitinized trough, lightly ehitinzed ventrally. laterally and on the dorsal apex for about one-third its length. Dorsally the second connecting membrane continnes posteriorly to the chitinized area. Although there are no chitinized plates to mark its position the median orifice appears to be at the apex of this membrane. The median stronts are attached to ventral-lateral extensions of the median lobe. The tegmen forms a thin ring, its strut very short.

Inthomomus squamosus Lee. Figs. 32 a \& b.
The median lobe is fully chitinized ventrally and laterally. Dorsally the chitin is confined to the apex and to an area behind a membranous lamen that bears the median orifice in its distal end. Median stuts are attached laterally to a ventral-like extension of the median lole. The tegmen is a $Y$ with long forks that hank the median struts. Inlhonomus cugenii Cano. Figs. 33 a \& 1.

The median lobe is a long, narrow, and fully chitinized ventrally and laterally. Dorsally the chitin is confined to a rather blunt apex and 10 an area behind a membranous lumen which bears the median orifice. This orifice is bordered by a lightly chitinized orificial plate. The median struts are lighty attached to the ventral surface of the median lobe. The tegmen is a large. but slender ring that surrounds the median struts.
Phyonomus nigrirostris (Fab.) Figs. 34 a \& b.
The median lobe is a broad chitinized scoop, the second comnertin:membrane extending into it dorsally for about half its distance. A large median orifice lies in the terminus of this membrane. The median struts articulate with the ventral surface of the median lobe. The tegnen is a the forks flanking the median struts. An inter-aedeagal structure is present within the flagellum.
Cryplorhyuchus parochus (Hbst.) Figs. 35 a \& b.
The median lobe is a chitin trough with the second connecting membranc extending into it dorsally for most of its distance. The median orifice, flanked by orificial plates, is near the apex of this membrane. Tmmediately behind the plates and within the internal sac 13 an inter-aedeagal structure. The median struts are attached to the ventral-lateral edge of the median lobe. The tegmen is a $Y$ with the forks flanking the median struts.

## Thytonomus posticus ( (rilll) Figs. 1 a, b \& c.

The median lobe is a chitin scoop with the second commecting membrame extending into it mid-dorsally with the median orifice locate? in the apex of this membrane. The median struts articulate with a rentral extension of the median lobe. The tegmen is a l' with the forks extending dorsally to flank the median struts. A L' shaped interacdeagal structure is present within the flagellum.
llypera punctutu (Fab.) Figs. 36 a \& D.
The median lobe is a chitinized scoop over ome half as browt as it is long. The second connecting membrane extends into it dorsally (1) near its apex where the median orifice is found. It is Aanked by the urificial plates. The tegmen is a Y , the forks flanking the median struts "hich in turn articulate with the ventral-lateral edges of the median lobe. A large inter-aedeagal structure is noted.
(ioutorhynchus sulcicollis (Payk.) Figs. 37 a \& 1 ).
The median lobe is a chitinized scoop with the second connectins: membrane extending into it for alout one half of its distance. The median orifice is found near the apex of this membrane. There are mamerons inter-atedeagat structures which are presumed to be a pard of the internal sac. The tegmen is a $Y$ with the forks flanking the median struts which are attached to a ventrat extension of the mediat lolve.

Tychius lineellus Lec. Figs. 38 a \& 1).
The median lobe forms an inverted chitinized trough which in largely chitinized dorsally and laterally, but ventrally the chitin is confincel to the periphery. There is, however, a membranous area near the dorsal apex which contains the median orifice. The median struts articulate with ventral-lateral projections of the median lobe. The tegmen is small and Y' shaped and lies below the median struts.
Rhinoncus fyrrhopus Boh. Rigs. 39 a \& B.
The median lobe forms an inverted chitin trough, densely chiti nizel laterally, lightly so dorsally with the ventral largely membranous. I smatl membranous lumen near the apex dorsally contains the median orifice. Median struts are attached to ventrat-lateral points of the median lobe. The tegmen is small and l' shaped with the forks fanking the median struts.

Sub Camily: Cabenmene
Cinarampristics of the Stb-famity: The median lohe usually
ionsists of a dorsal and a ventral plate which are separated laterally by a narrow strip of membrane. The median orifice lies in a membranous or a lighty chitinized area dorsally near the apex and is thanked log oriticial plates. In all forms the internal sac can be seen. The anomit and degree of chitinization both dorsally and ventrally is variable, witen this forms the chice difference between species. The median struts are attached or articulate with the anterior end of the thorsal plate. In most forms the two struts are joined for a variable distancr anterior to the point of articulation.

The tegmen forms a $I$ with the forks surromanding the median struts. The membrane survounding the tegmen in this area is chitinized, int some species decidedly so. Attached to the ventral aspect of this "slecee" is the spiculum gastrale a chitin rod that extends anteriorly and dorsally on the right side. The first and second connecting menbranes could not be separated one from the other by their attachment (1) the tegmen as in other forms as the tegmen lies well within the "sleeve." However, Sharp and Muir have noted this and have labeled the membranous area comecting the median lobe with the "sleeve" as the tirst connecting membrane and the "sleeve" or the chitinizer portion as the second connecting membranc. Subsequently Muir reversed this order and lissell adopted the revision. In this paper the reversed order wi Muir \& Bissell has been utilitzed.

Colendra pariulus Gill. Figs. 40 a \& b.
The median lobe consists of two plates, the dorsal is membranontis terminally, the ventral with an oblong membranous area medially. The median orifice is in the dorsal membranous area and is flanked by orilicial plates. Median struts articulate with the dorsal plates and are comnected for some distance behind the point of articulation. The firsi connecting membrane is lightly chitinized but is hardly discernible from the second. The spiculum gastrale is attached to this lightly chithionl "sleeve."
Calendra destructor Chitt. Figs. 41 a \& b)
The median lobe consists of two plates, both the dorsal and the ventral with membranous areas apically. The median orifice is in the dorsal membranous area and is bordered by orificial plates. Median struts articulate with the median lobe and are connected briefly anterior to the point of articulation. The first connecting membrane is decidedly chitinized with the spiculum gastrale attached to it.
Caleudra ochreus Lec. Figs. 42 a \& b.
The median lobe consists of two plates. the ventral fully chiti
nizerl, the dorsal with a membranous area terminally. Within this area lies the median orifice Hanked by small orificial plates. Median struts articulate with the dorsal plate and are connected for some distance anterior to point of articulation. The first comecting membrane is discermibly chitinized.

Calcudra aeac Walsh. Figs. 43 a $\&$ b.
The median lobe comsists of two plates, the dorsally fully chiti nized athough it is much more densely so laterally. The ventral plate is chitinized apically and laterally with a distinct membranous strip, extenting medially as an apparent continnation of the 2nd connecting: membrane. The median orifice which is dorsal and terminal is tlanked hy orificial plates of denser chitin. Median struts articulate with the dorsal plate and are connected for some distance anterior to the point of articulation. The first comecting membrane is markedly chitinized and bears the spiculum gastrale, and is marked dorsally by a $V$ shaped intrusion of the second connceting membrane. The internal sac is massed on the left side of the aedeagus just anterion to the median lobe. No race of the ejaculatory duct can be discerned through the menbrane.

Scyphophorus y'uccae Horn. Figs. 44 a \& b.
The median lobe consists of two plates, the ventral fully chitinized, much more densely so laterally. The dorsal plate is chitinized laterally and terminally the center consisting of a posterior extension of the second connecting membrane with the median orifice at the apex where it is flanked by orificial plates. Median struts articulate with the dorsal plate and are attached anterior to the point of articulation by a cross har, beneath which is found an inter-aedeagal structure. The first connecting membrane is well chitinized with the spiculum gastrale attached to it.

Rhodobacmus tredecimpunctalus (111.) Figs. 45 a \& b.
The median lobe is a single chitin trough the sides of which meet both anteriorly and posteriorly. Ventrally and laterally the structure is wholly chitinized, but dorsally a membranous strip extends down the center. The median orifice is found in the membranous area near the apex and is flanked ly orificial plates. The median struts are attached to a dorsal plate-like extension of the median lobe. Both connecting membranes are lightly chitinized and the "sleeve" although present, is not readily distinguished from the second connecting membrane. The point of attachment of the spiculum gastrale and the location of the
tegmen have been the deciding factor in arbitrarily labeling these fwo membranes.

## Family Scolitidae

Characteristics of the Family: The median lobe consists of a single chitinized plate the sides of which are inflexed to form a trough. The median orifice is located in a dorsal membranous area and an orificial plate is present. The median struts are attached differently in each of the two specimens examined. The tegmen is present as a simple ventral plate. Dorsally and laterally the connecting membranes are continuous and camot be distinguished except in reierence to their position to the tegmen.

Scolyus aentralis Lec. Figs. 46 a \& b.
The median lobe is a relatively deep chitinized trough, the edges almost meeting mid-dorsally. The median orifice is located in a membranous area dorsally and apically and is overlain by an orificial plate. The merlian struts are mid-lateral extensions of the anterior margins of the median lobe. The tegmen is a flat chitinized plate, slightly iorked anteriorly.

## Dendroctonus valens Lec. Figs. $47 \mathrm{a} \& \mathrm{~b}$.

The median lobe is a chitinized trough with parts of the eflges extending dorsally as paired "wings." Dorsally the second connecting membranc continues through the median lobe to its aper. An oriticial plate lies near the apex in this area with the median orifice located inmediately posterior to it. Anterior to the plate and within the internal sac are two inter-aedeagal structures. The median struts are lightly attached to the mid-lateral edges of the median lobe and appear to be joined at their points of origin anteriorly. The tegmen is aflat, $V$ shaped sclerite.

## TAXONOMY AND PHYLOGENY

In grouping the Rhynchophora on the basis of the study of the external genitalia of a limited number of species alone, the writer is aware of the definite limitations that exist. Even if the genitalia of the entire group had been examined no final conclusions regarding the taxonomy and phylogeny could be reached. As Macgillivary points out, all struçtures must receive serious consideration in determining the phylogeny of insects. This does not, however, rule out the wisdon of making studies of individual characteristics or of making interpretations of the information secured in such investigations since it is through such studies properly correlated with those of other parts, that
the eventual complete unterstanding of the various groups will be attainel. The interpretations that follow are not intended as represienting the final word in phylogeny of the species studied. Kather it is hoper that they will contribute to the general morphological knowlerge: of those species and the groups to which they belong.
( )n the basis of the external genitalia the Rhynchophora examined secm to fall into eight groups, the relationships of which are noted below. They are separated on the basis of the two chitinized segments of the aerleagus, the merlian lole and the tegmen. Whth other parts consiflered when a marked variation occurs.

The ledidae, the Brentidae and the group which includes the Ittelabinae. Rhymebitnae, Cytatinace (?), Pterocolinate, the and genus Notaris (Curculioninae) are all alike in one respect, that is, the median lole is composed of both a dorsal and a ventral "plate" each of Which is attached to a posterior fork of the median strut. The Belidae are set apart from the rest of the group by the distinctive strap-shaped dorsal piece of the median lobe as well as the large $X$ shaped cap-piece oi the tegmen. The lirentidae are distinctive in that the cap-piece is not firmly attached to its base, rather it articulates with it. The reduced cap-piece attached 10 a solid ring is characteristic of the Attelabinae group.

In none of the other forms examined was the median strut divided posteriorly. These forms with the single median struts are separated as follows: The Platystomidae are distinctive in that the tegminal cap-piece has a single posterior projection and is hirsute terminally: The Apioninae are set apart by a large tegminal cap-piece and a simple median lolve. The Calendrinac are separated from the
others on the basis of the partial or pronounced chitinization of the first comnecting membrane to which the spiculum gastrale is athacherl. The similarities of the Otiorhynchinae and the Curculioninae have been moted. The median lobe may be either a trough or a tube while the tegmen varies from a simply $I$ to a ring, often with paired lobes that nomally point posteriorly. The Scolytidae are by far the simpiest ni all the forms studied, the distinctive plate-like tegmen without a strut being sufficient to separate it from all others. The median lobe likewise is reduced to a simple trough with the lateral edges rather high.
loving \& Craighead after a study of the larvate of numerous Coleoptera have broken the Khynchophora down into two large groups, the l'latystomidea and the Curculionidea, the latter being divided into the families Rrentidae, Proterhinidae, Attelabidae. (Rhynchitinae and Attelabinae), Apionidae, Curculionidae, (Curculioninae \& Lissorhoptrinae), Calendridae, Platyporlidae, and Scolytidae. Belidae was not studied.

Ting, in his study of the mouth parts of Rhynchophora is in gencral agreement with Boving and Craighead. He does, however, add the Rhinomacerinae and the Pterocolinae to the Attelabidae of Boving and Craighead, presuming that the larval stages of these groups were not studied by those two investigators. Although one species of $\mathrm{Cy}-$ ladinae. Cylas formicarius (Fab.) was studied by Ting, he did not include it in with the Attelabidae. The same species was studied in this investigation and has been tentatively included in with the Attelabidae, although it does differ from the rest in that the tegminal cap-piece is bifurcate, while all the others are essentially undivided. Whether this characteristic is distinctive enough to separate it from the others is problematical, therefore its inclusion is only tentative.

There is no record of the genus Notaris being studied in either of the two investigations noted above. On the basis of the external genitalia it is more like the Attelabidae than it is the Curculionidae. The dorsal plate of the median lobe is considerably reduced, however, and a slight tendency toward the division of the tegminal cap-piece was noted. It may be that Notaris is an intermediate form between the two groups.

Within the Otiorhynchinae and the Curculioninae, which includes the balance of the Curculionidae investigated in this study according to the classification of Boving and Craighead, which has been noted in the third supplement of Leng's Catalogue, the arrangement of the species differs somewhat from the arrangement adopted in the first edition. It should be noted, therefore, that this does not imply that
such an arrangement of the family should be adopted. The reduction of the tegmen from a bilobed ring to a simple $I$ shaped strut is easy to follow, but this is not always in agreement with a similar simplifi cation of the median lobe.

## SUMMMARI

1. On the basis of the comparative morphology of the external genitalia the Khynchophora investigated seem to fall into eight groups. In general this is in agreement with that suggested by Roving and Craighead and by Ting.
2. The genus Notaris seems to be more closely related to the Attelabidae than to the Curculionidae.
3. The Cyladinae show simitarities to the Attelabidae, but also show differences that make its inclusion within the group questionable.
4. Assuming that the common opinion that structures have become more simple as structures have evolved, or more specifically that the statement by Muir that the evolution of the genitalia in Coleoptera has been from the complex to the simple, is correct, the Belidae, Brentidae and the Attelabidae group are the most primitive and the Scolytidae are the most recent.
5. Where closely related species of the same genus were investigated, discernible differences were noted in the construction of the external genitalia. It appears, therefore, that investigation of the genital structures should be utilized as a means of identifying the variots. species of Rhynchophora.
